1. INTRODUCTION

A new paradigm within the building sector is currently rising in Spain. changing from new construction activities to building rehabilitation works. This change is motivated by recent legislative requirements such as the Spanish Energy Efficiency Certification Royal Decree. which will lead to a considerable increase of building rehabilitation works. The expected increase of building retrofitting works will generate vast amounts of construction and demolition waste (CDW). which will need to be correctly managed by promoting ways for reuse or recycling in order to meet the requirements set by the European Community for 2020. Also, many initiatives and research have been found focusing on the development of new building materials and products that are less expensive, more durable, with higher quality and more environmentally friendly. In this sense, the following studies can be highlighted:

- Gutierrez-Gonzalez et al. designed a lightweight plaster material with enhanced thermal properties made with polyurethane foam wastes [1];
- · Parres et al. analysed the use of fibre and microfiber obtained from shredded tires to reinforce gypsum composites [2];
- Ge et al. investigated the influence of aggregate gradation, sand-to-PET ratio and curing conditions on physical and mechanical properties of recycled PET mortar [3];
- Abdulkadir and Ramazan analysed the effects of using recycled waste expanded polystyrene foam, as a potential aggregate in lightweight concrete [4].

3. MATERIALS & METHODS

The aim of this research is to analyze the feasibility of using CDW —from building retrofitting works— as raw materials for gypsum materials manufacture. To this end. several tests (density. mechanical strength. etc.) were performed to gypsum samples containing different building retrofitting waste categories (insulation. paper. plastic. ceramic tiles. etc.).

4. RESULTS

Results have been summarized in the following graphics for density. flexural strength. compressive strength and Shore C Surface Hardness.

Table 1 shows the different CDW materials analyzed in this study and their percentage of addition and format.

To analyze the feasibility of using these CDW as raw materials for gypsum materials manufacture the different gypsum composites containing these CDW were analyzed by elaborating prismatic specimens (160x40x40) mm³. These composites were tested by their density in dry state. their flexural and compressive strength after 7 days and their Shore C surface hardness as specified in the European Standards EN 13279-2 [5] and UNE 102039 [6]. All results were compared with the results obtained with a reference sample made with no additives. to evaluate the advantages and disadvantages of incorporating the different CDW aggregates.

These figures show that density can be increased by adding ceramic waste and paper. while the incorporation of expanded polystyrene and cellular glass helps decreasing density up to almost 30% over the reference value.

Flexural and compressive strength have a similar behaviour. Both strengths values increase when ceramic waste --from perforated bricks-- or glass wool are added. and decrease considerably with the addition of paper and expanded polystyrene.

Shore C Surface Hardness only increases significantly with the addition of glass wool. plastic fibres and polypropylene.

5. CONCLUSIONS

After analyzing all test results. it is seen that manufacturing gypsum composites with CDW has obtained positive results. In this sense, the use of ceramic waste from perforated bricks in gypsum composites improves the general properties of the gypsum material. In addition. mineral wool. plastic fibers and polypropylene can be used to reinforce gypsum and the use of expanded polystyrene helps reducing density. On the other hand, waste paper has been studied in different formats. but no significant results were obtained.
